## HIGHLIGHTS

- Neutralization by NH<sub>3</sub> is the controlling factor for the efficient heterogeneous formation of sulfate.
- O<sub>3</sub> and NO<sub>2</sub> mixture shows a strong synergetic effect on the heterogeneous oxidation of SO<sub>2</sub> only under NH<sub>3</sub>-rich conditions.
- The sharply rising ALWC caused by nitrate is responsible for the synergetic effect of mixed oxidants on sulfate formation.

## ABSTRACT

Extremely high levels of atmospheric sulfate aerosols have still frequently occurred in China especially in winter haze periods and often been underestimated by models due to some missing formation mechanisms. Here we investigated the heterogeneous reaction dynamics of SO<sub>2</sub> oxidation by the abundantly co-existing O<sub>3</sub> and NO<sub>2</sub> in the urban atmosphere of China by using a laboratory smog chamber simulation technique. Our results showed that with an increase of NH<sub>3</sub> concentrations from 0.05 ppm to 1.5 ppm, SO<sub>2</sub> oxidation by O<sub>3</sub> can be greatly promoted and lead to an exponential increase of diameter growth factor (GF) of particles in the chamber from 1.29 to 1.98 for NaCl seeds and from 1.20 to 1.60 for (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> seeds, along with an increasing uptake coefficient ( $\gamma$ ) of SO<sub>2</sub> from  $4.47 \times 10^{-5}$  to  $1.52 \times 10^{-4}$  on NaCl seeds and from  $2.32 \times 10^{-5}$  to  $5.74 \times 10^{-5}$  on (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> seeds, respectively. The heterogeneous production of sulfate from oxidation of SO<sub>2</sub> under NH<sub>3</sub>-rich conditions by O<sub>3</sub> and NO<sub>2</sub> mixture in the chamber was 2.0–3.5 times the sum of sulfate from SO<sub>2</sub> oxidations by O<sub>3</sub> and NO<sub>2</sub>, suggesting a strongly synergetic effect of the mixed oxidants on the heterogeneous oxidation of SO<sub>2</sub>, which can cause rapid formation of (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> and NH<sub>4</sub>NO<sub>3</sub> and is responsible for the explosive growth of PM<sub>2.5</sub> in the winter haze period of China. Our chamber results further showed that such synergetic process is only efficient under NH<sub>3</sub>-rich conditions, clearly indicating that the combined controls on O<sub>3</sub>, NO<sub>x</sub> and NH<sub>3</sub> are necessary for further mitigating the PM<sub>2.5</sub> pollution in China.

## 1. Introduction

Sulfate is one of the most abundant particles in the atmosphere, which is mainly generated via a series of multiphase chemical reactions (Sun et al., 2019; Zhang et al., 2013) and plays important roles in the global changes in climate and environment. Although the relative contribution of nitrate to particle pollution in China has increased quickly in the past decade and dominated the mass concentration of PM<sub>2.5</sub> due to the decrease in SO<sub>2</sub> emissions, concentration of atmospheric sulfate in the country is still very high, especially in winter haze periods (Lin et al., 2020; Ma et al., 2020; Wang et al., 2018a; Xie et al., 2020). The explicit mechanisms for the explosive growth of fine particles (PM<sub>2.5</sub>) in China during severe haze periods are still under debate, of which rapid formation of sulfate is one of the focus.

Extensive studies have explored the formation mechanisms of atmospheric sulfate aerosols. Oxidation processes of SO<sub>2</sub> by O<sub>3</sub> (Li et al., 2007), H<sub>2</sub>O<sub>2</sub> (Warneck, 1999), NO<sub>2</sub> (Ge et al., 2019b; Wang et al., 2016) and the catalytic oxidation by transitional metals ion (Alexander et al., 2009) in cloud and aerosol droplets are thought to be the main sulfate formation pathways by model simulations and laboratory investigations. However, in comparison with the field measurements the sulfate predictions by models tend to be underestimated, suggesting there are some unknown mechanisms on the sulfate formation (Gao et al., 2016a; Gao et al., 2016b). The role of different oxidants in atmospheric sulfate formation process is dependent on the different environmental conditions such as aerosol liquid water content (ALWC), aqueous phase acidity and oxidant levels. For example, a Lagrangian trajectory model study showed that at an initial pH of 5.0, H<sub>2</sub>O<sub>2</sub> contributed about 86% to the total oxidation of SO<sub>2</sub> in cloud, followed by O<sub>3</sub> (~13%). However, at pH of 6.5 conditions, 74% of sulfate in cloud was from the reaction of H<sub>2</sub>O<sub>2</sub> with S(IV) and 25% from O<sub>3</sub> (Venkataraman et al., 2001). Recently, both model and laboratory investigations showed that the contribution of NO<sub>2</sub> to sulfate formation in China during haze events is more important than other pathways when aerosol pH is higher than 5.4, which is the dominant formation pathway of sulfate in the atmosphere over the major part of North China Plain (Tao et al., 2020; Wang et al., 2016). Based on the Atmospheric Composition-Climate Model, Unger et al. (Unger et al., 2006) found that a 20% increase of sulfate pollution would be driven by the increasing of O<sub>3</sub> from 35 to 60 ppb. A most recent study simulated by the WRF-Chem-AWAC model suggested that the spatio-temporal variability of aerosol pH, different chemical regimes, reactant concentrations and meteorological conditions all have influences on the sulfate formation (Tao et al., 2020).

Because of the promulgation of the Clean Air Action laws in 2013, PM<sub>2.5</sub> pollution in China has been significantly mitigated. Zhai et al. (2019) reported that the annual concentrations of PM<sub>2.5</sub> across China decreased by 30–50% over the period of 2012 to 2018. Such changes have resulted in an increase in oxidizing capacity of the Chinese urban atmosphere, which is characterized by the abundantly co-existing O<sub>3</sub> and NO<sub>2</sub> in the country (Li et al., 2019). Under favorable meteorological conditions, the co-occurrence of O<sub>3</sub> and NO<sub>2</sub> may promote the formation of secondary aerosols, initiating an explosive growth of PM<sub>2.5</sub> in Chinese megacities. For example, Wu et al. (2020b) observed that the pollution events with O<sub>3</sub> and NO<sub>2</sub> simultaneously exceeding 100 µg m<sup>-3</sup> frequently occurred in Shanghai during the autumn of 2019 and was often accompanied with sharp increases of PM<sub>2.5</sub> concentrations (Wu et al., 2020b).

In order to improve our understanding on the strategies for a further mitigation on the fine particle pollution in China, here we investigated the dynamics of the heterogeneous formation process of sulfate via SO<sub>2</sub> oxidation by O<sub>3</sub> and NO<sub>2</sub> mixture by using a smog chamber technique. Our results showed a strongly synergetic effect of O<sub>3</sub> and NO<sub>2</sub> on sulfate formation, highlighting the importance of combining controls on the emissions of NOx and related precursors in the country.

## 2. Experimental section

### 2.1. Materials and methods

Simulation experiments in this study were performed in a 1.1 m<sup>3</sup> smog chamber, which is composed of a 5.6 mm thick acrylic outer shell and 0.13 mm Teflon inner bag (Fig. S1). The experimental details have been described elsewhere (Ge et al., 2019b; Wang et al., 2016). Here we only give a brief description as follows.

Zero air, produced by the Zero Air Supply (Model 111 and Model 1150, Thermo Scientific), was used as background gas in all the experiments. Many field observations reported that wintertime severe haze events in China frequently occurred with a relative humidity (RH) larger than 90% (Ge et al., 2019b; Wang et al., 2016; Wu et al., 2019). Thus, in this work we chose a RH of 90 ± 1% condition in the chamber to mimic the sulfate formation by introducing a humid vapor flow produced from zero air bubbling through ultrapure water (Milli Q, 18.2 MΩ, Millipore Ltd., USA). Seeded particles were generated by a single jet atomizer (7388SJA, TSI) from a bulk solution containing NaCl or (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>. Then, the seeded aerosols were dried by passing through two tandem Nafion dryers. Afterwards, the aerosol particles with a diameter of 100 nm were selected by a Differential Mobility Analyzer (DMA) and introduced into the chamber. The initial concentration of the selected seeds in the chamber was about 5 × 10<sup>4</sup> cm<sup>-3</sup>. The reactant gases including SO<sub>2</sub>, NO<sub>2</sub>, and NH<sub>3</sub> were purchased from Air Liquide Holding Co., Ltd. (China) and were injected individually into the chamber using a glass syringe. Ozone was generated by an ozonizer (LT-100, China) via ionizing high purity oxygen (99.999%) and introduced into the chamber directly. All the experiments in this work were conducted at 298 K (room temperature) and 1 atm.

### 2.2. Monitoring analysis

Reactant gases (SO<sub>2</sub>, NOx, O<sub>3</sub>) in the chamber were monitored by Thermo scientific analyzers (SO<sub>2</sub>, NOx, O<sub>3</sub> analyzers), respectively. The Scanning Mobility Particle Sizer (SMPS, model 3082) was used to measure the size parameters of aerosols including size distribution, number and mass concentrations. The chemical compositions of the particles in the chamber were analyzed by a high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS, Aerodyne Company, USA).

### 2.3. Smog chamber experiments

To investigate the synergistic oxidation effect of O<sub>3</sub> and NO<sub>2</sub> on sulfate formation in the urban atmosphere of China during the haze development process, experiments about SO<sub>2</sub> oxidation by O<sub>3</sub> or/and NO<sub>2</sub> were conducted. In the current work, NaCl and (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> were chosen as seeds. The initial conditions of the simulation experiments are listed in Table S1.

The aims of experiments 1–10 were to compare the effects of different seed particles on sulfate formation via SO<sub>2</sub> oxidation by O<sub>3</sub>, and the role of varied concentrations of NH<sub>3</sub> in sulfate formation during this process were further studied. As control experiments, the experiments of SO<sub>2</sub> oxidized by NO<sub>2</sub> (exp. 11–12) were conducted based on our previous work (Ge et al., 2019b). The process of SO<sub>2</sub> oxidation by mixed oxidants (O<sub>3</sub> + NO<sub>2</sub>) with 1 ppm NH<sub>3</sub> in the presence of NaCl or (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> seed particles were studied by exp.13–16. To mimic the meteorological conditions of severe haze in China that are characteristic of very weak solar radiation due to high RH conditions and heavy particle pollution, all the chamber experiments in this work were performed under RH of 90 ± 1% and dark conditions by using an anti-UV cloth hood covering the chamber.

### 3. Results

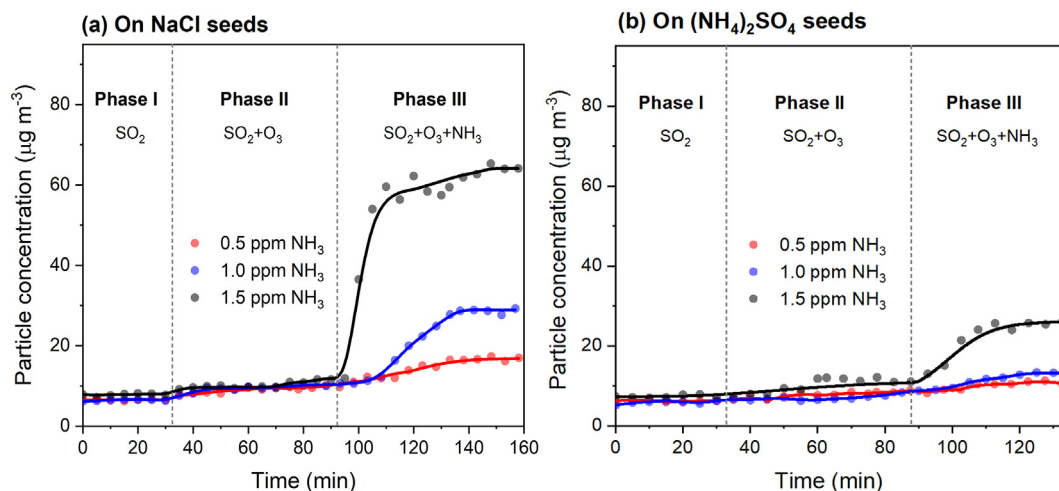

#### 3.1. Effects of $\text{NH}_3$ on $\text{SO}_2$ oxidation by $\text{O}_3$

Heterogeneous oxidation of  $\text{SO}_2$  by  $\text{O}_3$  in wet aerosols is one of the major formation pathways of atmospheric sulfate in the planetary boundary layer, such an aqueous phase oxidation is highly pH dependent (Reilly et al., 2001) and thus can be significantly promoted under  $\text{NH}_3$ -rich conditions. To quantitatively investigate the promoting effects of  $\text{NH}_3$  on the heterogeneous  $\text{SO}_2$  oxidation by  $\text{O}_3$ , NaCl and  $(\text{NH}_4)_2\text{SO}_4$  seeds, which are two common particles in the urban atmosphere of China (Ding et al., 2020; Wang et al., 2014; Wang et al., 2013), were exposed to  $\text{SO}_2$  and  $\text{O}_3$  for about 2 h, respectively, and measured for chemical composition by HR-ToF-AMS and size distribution by SMPS. As shown in Fig. 1, strong signals of fragment ions ( $m/z = 96, 81, 80, 64, 48$  and  $32$ ) were detected after the exposure of the seeded NaCl particles to  $\text{SO}_2$  in the presence of  $\text{O}_3$ , demonstrating that  $\text{SO}_4^{2-}$  was the product of the reaction of  $\text{SO}_2$  with  $\text{O}_3$ . As seen in Fig. 2a, mass concentration of particles in the chamber during Phase I kept constant after exposing NaCl seeds to  $\text{SO}_2$  for about 30 min and no any signal of sulfur-containing ions was observed by the HR-ToF-AMS, suggesting that no

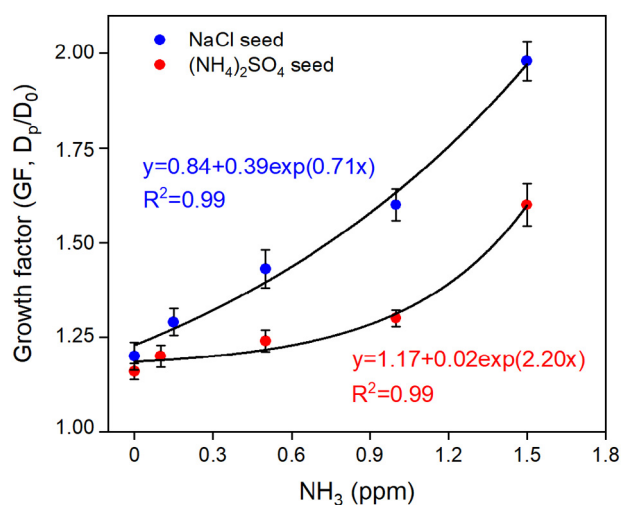

detectable amount of sulfate or sulfite was formed via the reaction of  $\text{SO}_2$  with the background gas ( $\text{O}_2 + \text{N}_2$ ) on the seeds or hydrolysis of  $\text{SO}_2$  in the aerosol aqueous phase under the  $90 \pm 1\%$  RH conditions (Fig. 2a, Phase I). When  $\text{O}_3$  was introduced into the chamber, the mass concentration of particles increased by  $4.05 \pm 1.19 \mu\text{g m}^{-3}$  in the  $\text{SO}_2/\text{O}_3/\text{NaCl}$  system, and the dry diameter of particles in the chamber grew from 101.8 nm to 126.3 nm (Fig. 2a, Phase II), which was due to the formation of  $\text{H}_2\text{SO}_4$  on the aerosol aqueous phase through oxidation of  $\text{SO}_2$  by  $\text{O}_3$ . A similar phenomenon was also observed for the  $\text{SO}_2/\text{O}_3/(\text{NH}_4)_2\text{SO}_4$  system (Fig. 2b, Phase I and Phase II), in which concentration of particles in the chamber increased by  $2.83 \pm 0.60 \mu\text{g m}^{-3}$  and the corresponding size of the seeded  $(\text{NH}_4)_2\text{SO}_4$  particles increased from 101.8 nm to 117.6 nm in a dry diameter. Such an increase in particle size in the absence of  $\text{NH}_3$  was not observed by our previous studies (Ge et al., 2019b; Wang et al., 2016), which exposed the two types of seeds to  $\text{SO}_2$  and  $\text{NO}_2$  under the same experiment conditions, indicating that the oxidizing ability of  $\text{O}_3$  to  $\text{SO}_2$  is stronger than that of  $\text{NO}_2$ .

A significant increase of particle concentration was observed when  $\text{NH}_3$  was subsequently introduced into the chamber (Fig. 2a, Phase III). When the concentration of  $\text{NH}_3$  in the chamber varied from 0.05–1.5 ppm, the increase in concentration of particles varied from  $8.93 \mu\text{g m}^{-3}$  to  $55.58 \mu\text{g m}^{-3}$  for the NaCl seeds, which was 2.2 to 13.6 times higher than that in the absence of  $\text{NH}_3$  (Fig. 2a, Phase II). The formed  $\text{H}_2\text{SO}_4$  was neutralized by  $\text{NH}_3$  into  $(\text{NH}_4)_2\text{SO}_4$ , which could decrease aerosol acidity and thus promoted the heterogeneous oxidation of  $\text{SO}_2$  by  $\text{O}_3$ . As for the  $(\text{NH}_4)_2\text{SO}_4$  seeds, when  $\text{NH}_3$  increased from 0.5 ppm to 1.5 ppm, the increase in concentration of particles in the chamber varied from  $3.71 \mu\text{g m}^{-3}$  to  $18.61 \mu\text{g m}^{-3}$  (Fig. 2b, Phase III), which is 1.3–6.6 times higher than that in the Phase II period (Fig. 2b, Phase II).

Fig. 3 shows the growth factor (GF) of particles in the chamber as a function of  $\text{NH}_3$  levels. The GF of both NaCl and  $(\text{NH}_4)_2\text{SO}_4$  seeds showed an exponential increase with an increase of  $\text{NH}_3$  levels, suggesting the promoting effect of  $\text{NH}_3$  on the sulfate formation. The GF of NaCl seeds is about 10–30% larger than that of  $(\text{NH}_4)_2\text{SO}_4$  seeds, indicating the more efficient production of sulfate with NaCl seeds compared to  $(\text{NH}_4)_2\text{SO}_4$  seeds. At  $90 \pm 1\%$  RH conditions the hygroscopic growth factor of 100 nm NaCl particles is 2.3 and larger than that (1.48) of 100 nm  $(\text{NH}_4)_2\text{SO}_4$  particles. We used the ISORROPIA-II thermodynamic model to further calculate the hygroscopicity of seeded particles in our chamber. The results showed that at 90% RH conditions the aerosol liquid water content of per mass of particles (ALWC/mass) in the chamber is 9.7 for the NaCl seeds and 3.09 for the  $(\text{NH}_4)_2\text{SO}_4$  particles, suggesting that NaCl is more hygroscopic and its higher ALWC is favorable for the

**Fig. 2.** Variations in mass concentration of particles in the chamber during the successive exposures of the seeds to  $\text{SO}_2$ ,  $\text{O}_3$  and  $\text{NH}_3$  ((a) NaCl seeds with a 100 nm diameter and (b)  $(\text{NH}_4)_2\text{SO}_4$  seeds with a 100 nm diameter).

**Fig. 3.** The growth factor of seeded particles in the chamber as a function of  $\text{NH}_3$  levels after the exposure to  $\text{O}_3$  (0.6 ppm) and  $\text{SO}_2$  (0.7 ppm) for 2.5 h at  $90 \pm 1\%$  RH conditions ( $D_0$  and  $D_p$  are the dry diameters of particles in the chamber before and after the exposure, respectively).

heterogeneous formation of sulfate (Badger et al., 2006; Peng et al., 2016). Besides, another proposed chemistry mechanism in NaCl aqueous phase has been elucidated that  $\text{O}_3$  can react with  $\text{Cl}^-$  on the surface to form  $\text{OH}^-$  (Faxon and Allen, 2013; Keene et al., 1990; Li et al., 2007). The alkaline surface can greatly promote the hydrolysis of  $\text{SO}_2$ . In contrast, the weakly acidic  $(\text{NH}_4)_2\text{SO}_4$  could be unfavorable to the hydrolysis of  $\text{SO}_2$  in liquid phase (Wang et al., 2018a). Therefore, heterogeneous oxidation of  $\text{SO}_2$  by  $\text{O}_3$  proceeded more efficiently on the NaCl seeds.

Based on the particle compositions measured by HR-ToF-AMS, the pH value and ALWC of particles in the chamber at the end of the experiments were calculated by using the ISORROPIA II thermodynamic equilibrium model with the assumption of aerosol in metastable state (Wang et al., 2018a). The acidity of neutral NaCl seeds sharply decreased from pH = 7 to pH = 0.7 when NaCl seeds were exposed to 0.7 ppm  $\text{SO}_2$  in the absence of  $\text{NH}_3$ . Researchers have verified that  $\text{NH}_3$  plays an effective role in particle formation with sulfuric acid because of their basicity (Benson et al., 2009; Chen et al., 2018a; Chen et al., 2016; DePalma et al., 2014; Lehtipalo et al., 2016; Qiu et al., 2011; Qiu and Zhang, 2013). With the neutralization of  $\text{NH}_3$ , the acidity

of particles decreased and was favorable for sulfate formation sustainably in the acidified NaCl droplets.  $\text{NH}_3$  could decrease aerosol acidity effectively, varied from pH = 4.5 in experiments with 0.05 ppm  $\text{NH}_3$  to pH = 5.6 with 1.0 ppm  $\text{NH}_3$  for the  $\text{SO}_2/\text{O}_3/\text{NH}_3/\text{NaCl}$  system (Fig. 4a). Similar increasing pH trend was also observed for  $(\text{NH}_4)_2\text{SO}_4$  seeds, of which the pH of aerosols changed from 3.6 under 0.1 ppm  $\text{NH}_3$  to 4.8 under 1.5 ppm  $\text{NH}_3$  (Fig. 4b).

The reactive uptake coefficients ( $\gamma$ ) of  $\text{SO}_2$  on the two types of seeded particles with various concentrations of  $\text{NH}_3$  can be calculated based on the following Eq. (E1):

$$\frac{d[\text{sulfate}]}{dt} = k[\text{SO}_2(\text{g})] = \frac{1}{4} \gamma C S [\text{SO}_2(\text{g})] \quad (\text{E1})$$

where [sulfate] is the molar concentration of sulfate produced during  $t$  reaction time period,  $\gamma$  is the uptake coefficient of  $\text{SO}_2$ ,  $C$  is the mean molecular speed,  $S$  is the aerosol surface area, and  $[\text{SO}_2(\text{g})]$  is  $\text{SO}_2$  concentration in the gas phase. As shown in Table 1, in the  $\text{SO}_2/\text{O}_3/\text{NH}_3/\text{NaCl}$  system, the  $\gamma$  of  $\text{SO}_2$  for sulfate formation under different  $\text{NH}_3$  levels (0.05–1.5 ppm) was in the range of  $4.47 \times 10^{-5}$ – $1.52 \times 10^{-4}$ , while the  $\gamma$  was in the range of  $2.32 \times 10^{-5}$ – $5.74 \times 10^{-5}$  in the  $\text{SO}_2/\text{O}_3/\text{NH}_3/(\text{NH}_4)_2\text{SO}_4$  system, suggesting that the uptake of  $\text{SO}_2$  on both NaCl and  $(\text{NH}_4)_2\text{SO}_4$  seeds increased with increasing concentrations of  $\text{NH}_3$ . Thus, more  $\text{NH}_3$  could promote the formation rate of sulfate in the atmosphere.

### 3.2. Synergistic effects of $\text{O}_3$ and $\text{NO}_2$ on sulfate formation under $\text{NH}_3$ -rich conditions

To explore the synergetic effect of mixed oxidants of  $\text{O}_3$  and  $\text{NO}_2$  on sulfate formation, experiments with  $\text{NO}_2$  introduced into the chamber were further conducted based on the process of  $\text{SO}_2$  oxidation by  $\text{O}_3$ . Fig. 5 shows the temporal variations in dry diameter and composition of particles in the chamber. The experimental results showed that particle sizes further increased after introducing  $\text{NO}_2$ , and a more obvious increase can be obtained when  $\text{NH}_3$  was introduced into the chamber based on the reactions of  $\text{SO}_2$  with  $\text{O}_3$ . Due to the reactions of  $\text{SO}_2$  with  $\text{O}_3$ , the mean diameter of NaCl particles grew from 117.6 nm (Fig. 5a, Phase I). When 0.3 ppm  $\text{NO}_2$  was subsequently introduced into the chamber, the mean diameter of particles grew dramatically to 259.5 nm (Fig. 5a, Phase II). A further shift of particle diameter to 371.8 nm was observed when 1.0 ppm  $\text{NH}_3$  was introduced into the chamber (Fig. 5a, Phase III). A similar increasing pattern of particle sizes was also observed for the seeded  $(\text{NH}_4)_2\text{SO}_4$  particles, which

**Fig. 4.** pH values of particles in the chamber with different  $\text{NH}_3$  concentrations after the exposures of (a) NaCl seeds and (b)  $(\text{NH}_4)_2\text{SO}_4$  seeds to  $\text{SO}_2$  (0.7 ppm) and  $\text{O}_3$  (0.6 ppm) under  $90 \pm 1\%$  RH conditions for 2.5 h.

<sup>a</sup> Surface area is the surface area of particles in the chamber during the exposure.

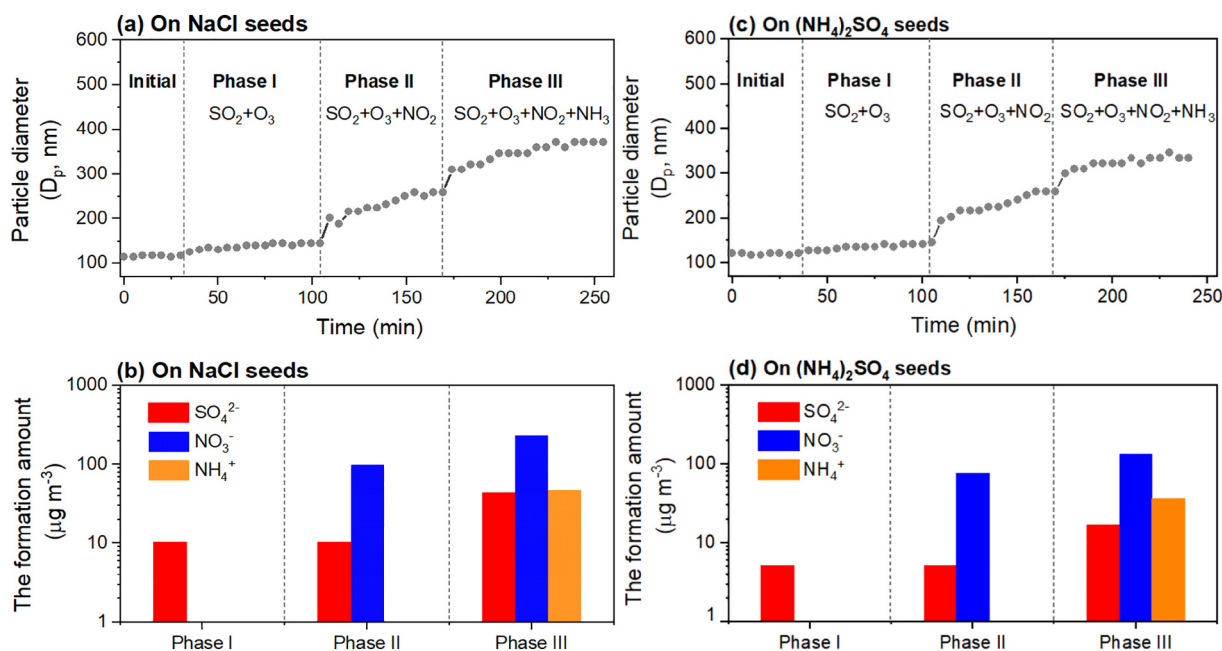

increased from 121.9 nm to 140.7 nm after the reactions of SO<sub>2</sub> with O<sub>3</sub> (Fig. 5c, Phase I), then grew sharply to 259.5 nm after introducing NO<sub>2</sub> into the chamber (Fig. 5c, Phase II), and further shifted to 333.8 nm in the presence of 1.0 ppm NH<sub>3</sub> (Fig. 5c, Phase III).

As shown in Fig. 5b, there was 10.28 μg m<sup>-3</sup> of SO<sub>4</sub><sup>2-</sup> formed in the Phase I period due to the reactions of SO<sub>2</sub> with O<sub>3</sub> on the wetted NaCl seed surface. When NO<sub>2</sub> was subsequently introduced into the chamber, abundant NO<sub>3</sub><sup>-</sup> (99.83 μg m<sup>-3</sup>) (Fig. 5a and b, Phase II) was generated but concentration of SO<sub>4</sub><sup>2-</sup> was almost entirely equal to that in Phase I. Since no NH<sub>3</sub> was introduced in the two stages, SO<sub>4</sub><sup>2-</sup> and NO<sub>3</sub><sup>-</sup> on the seeded particles in Phase I and Phase II mainly existed as H<sub>2</sub>SO<sub>4</sub> and HNO<sub>3</sub>, respectively, and the particle growth was caused by the accumulation of both acids on the seeds (Fig. 5b, Phase I and Phase II). After introducing 1.0 ppm NH<sub>3</sub> into the chamber, sharply increased concentrations of SO<sub>4</sub><sup>2-</sup> (44.07 μg m<sup>-3</sup>, Fig. 5b), NO<sub>3</sub><sup>-</sup> (233.81 μg m<sup>-3</sup>) and NH<sub>4</sub><sup>+</sup> (67.93 μg m<sup>-3</sup>) were observed, leading to a rapid growth in the diameter of seeded particles (Fig. 5a, Phase III). Abundant SO<sub>4</sub><sup>2-</sup>, NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup> were also observed in the experiments with (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> as the seeds, which were 17.05 μg m<sup>-3</sup>, 131.95 μg m<sup>-3</sup>, and 36.37 μg m<sup>-3</sup> under the 1.0 ppm NH<sub>3</sub> conditions, respectively (Fig. 5c

and d). O<sub>3</sub> in the chamber can react with NO<sub>2</sub> and form N<sub>2</sub>O<sub>5</sub>, which is highly reactive and can quickly be hydrolyzed into HNO<sub>3</sub> on the hygroscopic surface (Chen et al., 2018b; McDuffie et al., 2018). Gaston et al. reported that reactive uptake is the main pathway for N<sub>2</sub>O<sub>5</sub> diffused into (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> droplets to form HNO<sub>3</sub>. However, a near-surface reaction between absorbed N<sub>2</sub>O<sub>5</sub> with Cl<sup>-</sup> in NaCl droplets dominated the uptake of N<sub>2</sub>O<sub>5</sub>, which is much faster than the diffusion process of N<sub>2</sub>O<sub>5</sub> with H<sub>2</sub>O (Gaston and Thornton, 2016). Thus, more nitrate can be formed on NaCl seeds than on (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> seeds. The formed NH<sub>4</sub>NO<sub>3</sub> can absorb more water vapor and in turn further promote the heterogeneous formation of (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> and NH<sub>4</sub>NO<sub>3</sub> (Phase III in Fig. 5b and d, respectively).

As shown in Fig. 5, O<sub>3</sub> and NO<sub>2</sub> did not show synergistic effects on sulfate formation in the absence of NH<sub>3</sub>, although HNO<sub>3</sub> could be formed via the reaction of O<sub>3</sub> with NO<sub>2</sub>. Our previous work found that SO<sub>2</sub> oxidation by NO<sub>2</sub> cannot proceed efficiently under NH<sub>3</sub>-poor conditions (Ge et al., 2019b; Wang et al., 2018a; Wang et al., 2016), because SO<sub>2</sub> is a weak acid and the formed H<sub>2</sub>SO<sub>4</sub> could prevent SO<sub>2</sub> from dissolving into the acid solution. However, as seen in Fig. 5, O<sub>3</sub> and NO<sub>2</sub> showed a strong synergetic effect on sulfate formation in the presence of NH<sub>3</sub> in the chamber. Under the experiment conditions with NaCl as the seeds, the amount of sulfate (44.07 μg m<sup>-3</sup>) formed by the mixed oxidants of O<sub>3</sub> and NO<sub>2</sub> was 2.7 and 8.2 times higher than the amount of sulfate formed by the oxidation of O<sub>3</sub> or NO<sub>2</sub> alone in the presence of NH<sub>3</sub>, which was 16.42 μg m<sup>-3</sup> and 5.36 μg m<sup>-3</sup>, respectively (Table 2). Similar increased sulfate formation was also observed for the experiments with (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> as the seeds, clearly demonstrating a strong synergetic effect of the mixed O<sub>3</sub> and NO<sub>2</sub> on sulfate formation, which is effective only under NH<sub>3</sub>-rich conditions (Fig. 5, Phase III).

The uptake coefficients of SO<sub>2</sub> on NaCl or (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> seeds in experiments with mixed oxidants of O<sub>3</sub> and NO<sub>2</sub> in the presence of 1.0 ppm NH<sub>3</sub> were further calculated. As seen in Table 3, the value of γ on NaCl seeds was 9.25 × 10<sup>-5</sup>, and 4.24 × 10<sup>-5</sup> on (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> seeds, respectively, which is close to that in the experiments with O<sub>3</sub> as the oxidant. Due to the formation of sulfate, nitrate, and ammonium on the seeded particles and the subsequent absorption of water vapor, the surface area of aerosols in the chamber rapidly increased. As shown by the

**Fig. 5.** Evolution of size and composition of particles in the chamber (Initial concentrations of SO<sub>2</sub>, O<sub>3</sub>, NO<sub>2</sub>, NH<sub>3</sub> in the chamber were 0.8 ppm, 0.3 ppm, 0.3 ppm, 1.0 ppm, respectively) ((a) mean diameter of the seeded NaCl particles, (b) sulfate, nitrate and ammonium formed in the chamber after exposing NaCl seeds to the gaseous reactants, (c) mean diameter of the seeded (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> particles, and (d) sulfate, nitrate and ammonium secondarily formed in the chamber after exposing (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> seeds to the gaseous reactants).

**Table 2**Concentrations of  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$  and  $\text{NH}_4^+$  formed in the chamber after the exposure of NaCl or  $(\text{NH}_4)_2\text{SO}_4$  seeds to different oxidants for about 2.5 h in the presence of  $\text{NH}_3$ .

Oxidant	Seed <sup>a</sup>	RH (%)	$\text{SO}_2$ (ppm)	$\text{NH}_3$ (ppm)	$\Delta\text{SO}_4^{2-}$ <sup>a</sup> ( $\mu\text{g m}^{-3}$ )	$\Delta\text{NO}_3^-$ <sup>a</sup>	$\Delta\text{NH}_4^+$ <sup>a</sup>
$\text{O}_3$ (0.7 ppm)	NaCl	$90 \pm 1$	0.8	1.0	16.42	0.0	6.2
$\text{NO}_2$ (0.6 ppm)		$90 \pm 1$	0.8	1.0	5.36	0.0	2.0
$\text{NO}_2 + \text{O}_3$ (0.3 ppm + 0.3 ppm)	$(\text{NH}_4)_2\text{SO}_4$	$90 \pm 1$	0.8	1.0	44.07	234	68
$\text{O}_3$ (0.7 ppm)		$90 \pm 1$	0.8	1.0	4.87	0.0	1.8
$\text{NO}_2$ (0.6 ppm)		$90 \pm 1$	0.8	1.0	0.0	0.0	0.37
$\text{NO}_2 + \text{O}_3$ (0.3 ppm + 0.3 ppm)		$90 \pm 1$	0.8	1.0	17.05	132	36

<sup>a</sup>  $\Delta\text{SO}_4^{2-}$ ,  $\Delta\text{NO}_3^-$  and  $\Delta\text{NH}_4^+$  are the difference in the concentrations before and after the exposures.

Eq. (E1), the aerosol surface area is inversely correlated with the uptake coefficient  $\gamma$ . Thus, the  $\gamma$  for the mixed oxidants was not obviously greater than that for the single oxidant under the same experimental conditions.

## 4. Discussion

### 4.1. Reaction mechanisms for $\text{SO}_2$ oxidation by the mixed oxidants of $\text{O}_3$ and $\text{NO}_2$ under $\text{NH}_3$ -rich conditions

In the atmosphere sulfate is mainly formed by aqueous phase reactions of  $\text{SO}_2$  with  $\text{O}_3$ ,  $\text{NO}_2$ ,  $\text{H}_2\text{O}_2$ , OH radicals, and transitional metal ion catalysis (Cheng et al., 2016; Ma et al., 2013; Park et al., 2017; Wang et al., 2016). In the urban atmosphere, the heterogeneous oxidation of  $\text{SO}_2$  by  $\text{O}_3$  or  $\text{NO}_2$  follows the reaction pathways of (R1)–(R3) (Ge et al., 2019b; Li et al., 2007), among which the dominant role of  $\text{NO}_2$  on sulfate formation in the winter haze period of China was firstly pointed out by Wang et al. in 2016 (Wang et al., 2016), based on their field measurements and smog chamber simulation, and recently recognized by the atmospheric aerosol community with an increasing number of publications (Cheng et al., 2016; Tao et al., 2020; Wang et al., 2020; Xue et al., 2019). For example, by combing the field observation and numerical simulation, Tao et al. (Tao et al., 2020) found that  $\text{SO}_2$  oxidation by  $\text{NO}_2$  is the dominant pathway for sulfate formation in the megacity region of Beijing and the large area of Hebei Province, China.

A few field investigations have shown that  $\text{O}_3$ ,  $\text{NO}_2$  and  $\text{NH}_3$ , as well as VOCs in the urban atmosphere of China are abundantly co-existing (Vu et al., 2019; Zheng et al., 2018). Through this study, we found that the heterogeneous oxidation of  $\text{SO}_2$  by the mixture of  $\text{O}_3$  and  $\text{NO}_2$  to produce sulfate was much more efficient than by them single alone under  $\text{NH}_3$ -rich conditions. The synergistic effects of mixed  $\text{O}_3$  and  $\text{NO}_2$  on sulfate formation include a series of reaction processes as follows.

Firstly, besides the direct oxidation of  $\text{SO}_2$  by  $\text{O}_3$  and  $\text{NO}_2$ , respectively,  $\text{O}_3$  and  $\text{NO}_2$  in the atmosphere can react with each other, and  $\text{NO}_3$ , a highly reactive gas, would be generated during this process. The formed  $\text{NO}_3$  can further react with  $\text{NO}_2$  to form  $\text{N}_2\text{O}_5$  ((R4)–(R5)),

**Table 3**The uptake coefficient ( $\gamma$ ) of  $\text{SO}_2$  during the exposure of the 100 nm diameter of seeds to the mixed  $\text{NO}_2$  (0.3 ppm) and  $\text{O}_3$  (0.3 ppm) oxidant under  $90 \pm 1\%$  RH conditions.

Seed	$\text{NH}_3$ (ppm)	$\Delta\text{SO}_4^{2-}$ <sup>a</sup> ( $\mu\text{g m}^{-3}$ )	Surface area of particles ( $\text{cm}^2 \text{cm}^{-3}$ )	$\gamma$
NaCl	1.0	60.60	$8.56 \times 10^{-6}$	$9.25 \times 10^{-5}$
$(\text{NH}_4)_2\text{SO}_4$	1.0	23.44	$7.57 \times 10^{-6}$	$4.24 \times 10^{-5}$

<sup>a</sup>  $\Delta\text{SO}_4^{2-}$  is the difference of the sulfate concentration before and after the exposures.

which is the main source of nitrate at night (R6) (Liebmann et al., 2019; Wang et al., 2018b). During the process of heterogeneous reactions in the two  $\text{SO}_2/(\text{O}_3 + \text{NO}_2)/\text{NH}_3$ /seed systems, the quicker generation rate of nitrate led to massive nitrate formed, which was about one order of magnitude higher than sulfate before  $\text{NH}_3$  was introduced (Fig. 5, Phase II). The existence of  $\text{NH}_3$  can neutralize the acidity of particles, favoring more dissolution of acidic  $\text{NO}_2$  and  $\text{SO}_2$  (Yang et al., 2018). For example, in the experiments with NaCl seeds, the amount of nitrate increased from  $99.83 \mu\text{g m}^{-3}$  without  $\text{NH}_3$  to  $233.81 \mu\text{g m}^{-3}$  in the presence of  $\text{NH}_3$ . The strong hygroscopicity of nitrate can greatly enhance ALWC of particles in the chamber. In this work, the ALWC caused by nitrate formed in the chamber under the 1.0 ppm  $\text{NH}_3$  and  $90 \pm 1\%$  RH conditions was  $1049 \mu\text{g m}^{-3}$  for the NaCl seeds and  $956 \mu\text{g m}^{-3}$  for the  $(\text{NH}_4)_2\text{SO}_4$  seeds, respectively, which is about ten times higher than that under the oxidation by  $\text{O}_3$  or  $\text{NO}_2$  alone. Thus, the enhanced ALWC in aerosol particles by large amount of nitrate via the reactions of  $\text{O}_3$  and  $\text{NO}_2$  provides a favorable environment for sulfate formation in the  $\text{SO}_2/\text{O}_3/\text{NO}_2/\text{NH}_3$ /seed system (Ge et al., 2019a).

Secondly,  $\text{NO}_3$  is also an important oxidant product during the reaction process of  $\text{NO}_2$  with  $\text{O}_3$  (Brown and Stutz, 2012). Previous work had proposed that  $\text{NO}_3$  could enhance sulfate production via the series of reactions of (R7)–(R10) (Chameides, 1986; Feingold, 2002). Rudich et al. (1998) found that in polluted areas where high concentrations of dissolved S(IV) was present in the droplets, the role of  $\text{NO}_3$  in sulfate formation accounted for significant oxidation in the marine boundary layer; their simulation results showed that the relative contribution to sulfate by the uptake of 2.5 ppt  $\text{NO}_3$  accounted for about 50% of the sulfate formation by 40 ppb of  $\text{O}_3$  in 30 min (Rudich et al., 1998). These results suggest that S(IV) oxidation by  $\text{NO}_3$  probably also contributed to the synergetic effect observed by this work (Chameides, 1986; Hung and Hoffmann, 2015).

Thirdly, as seeds, NaCl particles are of greater effects on nitrate and sulfate formation than that of  $(\text{NH}_4)_2\text{SO}_4$  seeds. One of the reasons for this phenomenon is that NaCl has a stronger hygroscopicity ability than  $(\text{NH}_4)_2\text{SO}_4$  under the similar conditions (Hu et al., 2010; Park et al., 2008). Moreover, chloride ions in the NaCl droplets can react with  $\text{O}_3$  and  $\text{NO}_3$ , and the products during these processes may affect the oxidation of S(IV). Early researches have explored these reaction mechanisms and found that  $\text{Cl}_2$  could be produced during the process.

For example, using a chemical ionization mass spectrometer, Abbatt and Waschewsky (1998) observed an increase in the signal of  $\text{Cl}_2$  with a decline in the ozone signal in a flow tube study of heterogeneous reactions of  $\text{O}_3$  with NaCl aerosols (Abbatt and Waschewsky, 1998). Keene et al. (1990) used O—D photochemical model simulations of the marine surface air sampled to investigate the geochemical cycling of reactive Cl, and reported an accumulation of  $\text{Cl}_2$  during the night from the  $\text{O}_3$  reaction at NaCl surface (Keene et al., 1990). For reactions of chloride ions with  $\text{NO}_3$  radical, the formation of nitrate ions was observed by Schütze and Herrmann (2005) in a single drop experiment of the uptake of  $\text{NO}_3$  radical on NaCl solution (Schütze and Herrmann, 2005). Several researches further pointed out that  $\text{O}_3$  can react with  $\text{Cl}^-$  to generate an alkaline surface on the NaCl particle surface (R11), which can promote the hydrolysis of  $\text{SO}_2$  in the aqueous surface of aerosols (Faxon and Allen, 2013; Laskin et al., 2003; Li et al., 2007). The formed  $\text{NO}_3$  by reaction of  $\text{O}_3$  with  $\text{NO}_2$  can react with  $\text{Cl}^-$  to form Cl radical and  $\text{Cl}_2^-$  via a series of reactions ((R12)–(R13)). Both  $\text{Cl}_2^-$  and Cl radical can further oxidize  $\text{HSO}_3^-$  into sulfate ((R14)–(R15)) (Chameides, 1986; Hung and Hoffmann, 2015). Thus, in addition to the stronger hygroscopicity, the factors mentioned above may be also responsible for the stronger promoting effect of NaCl seeds on sulfate formation than that of  $(\text{NH}_4)_2\text{SO}_4$  seeds observed by the current chamber experiments.

In conclusion, the detailed chemical mechanisms for the synergetic effects of mixed  $\text{O}_3$  and  $\text{NO}_2$  on sulfate formation are very complicated. However, the role of  $\text{NH}_3$  observed in this work suggested that an enhanced hygroscopicity of aerosols due to the fast formation of  $\text{NH}_4\text{NO}_3$  by the reaction of  $\text{O}_3$  with  $\text{NO}_2$  and the subsequent absorption of water vapor could be the main reason, which significantly promoted the dissolution of all the reactants into the aerosol aqueous phase, enhancing the productions of sulfate and nitrate, as schematically plotted in Fig. 6.

#### 4.2. Implications for the haze formation in China

Sulfate is still one of the major components of  $\text{PM}_{2.5}$  in China especially during winter haze periods, although  $\text{SO}_2$  emission has been decreasing significantly in the past years (Ge et al., 2019b; Wu et al., 2020a; Xie et al., 2020). An explosive growth of  $\text{PM}_{2.5}$  that is dominated by  $(\text{NH}_4)_2\text{SO}_4$  and  $\text{NH}_4\text{NO}_3$  has still frequently occurred in Beijing, Shanghai and many other cities in China. However, the sharp increase in sulfate and nitrate concentrations during the Chinese haze development is often underestimated by current models especially for sulfate because of the lack of dynamic descriptions that can accurately track the aqueous phase formation process of sulfate in the country (Gao et al., 2016b). Concentrations of  $\text{PM}_{2.5}$  and sulfate in China have decreased significantly since 2013, because Chinese government has promulgated very strict controls on the emission of  $\text{SO}_2$  and smokes from coal-burning power plants in the country. However, due to the rapid increases in vehicle numbers,  $\text{NO}_x$  and  $\text{VOC}$  levels in China are still very high. Zhai et al. (2019) and Zhang et al. (2019) reported that compared to 2013, air pollutant levels across China in 2018 have decreased by 30–50% for  $\text{PM}_{2.5}$  and by 57–76% for  $\text{SO}_2$  but  $\text{NO}_x$  has decreased only by 21% in 2017 while  $\text{VOC}$  and  $\text{NH}_3$  emissions have kept constant and even slightly increased. The abundant co-occurrence of  $\text{NO}_x$  and  $\text{VOC}$  is favorable for photochemical reaction, resulting in high levels of  $\text{O}_3$  and  $\text{NO}_2$  in many regions of China such as Beijing and Shanghai (Li et al., 2019).

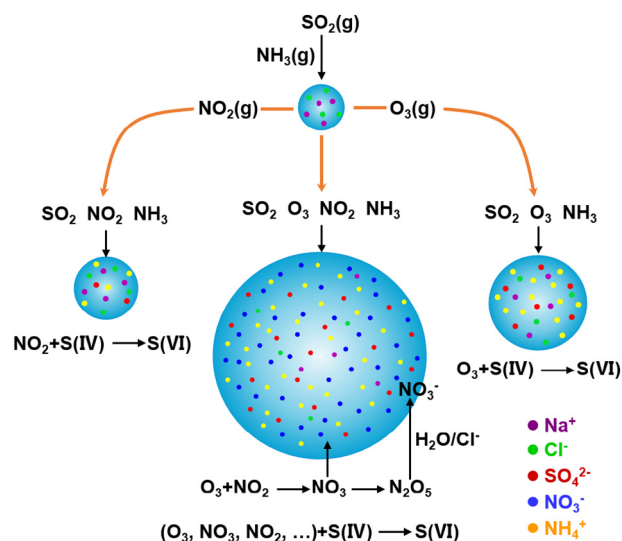

Fig. 6. A schematic plot for the heterogeneous formation mechanism of sulfate from the synergetic oxidation of  $\text{SO}_2$  by  $\text{NO}_2$  and  $\text{O}_3$ .

Based on the lab chamber simulation, this work has revealed a strongly synergetic effect of  $\text{O}_3$  and  $\text{NO}_2$  on sulfate formation, which can efficiently proceed under  $\text{NH}_3$ -rich conditions and lead to the rapid formation of hygroscopic secondary  $(\text{NH}_4)_2\text{SO}_4$  and  $\text{NH}_4\text{NO}_3$  aerosols in the haze periods of China. Our work suggested that combined measures to simultaneously control  $\text{O}_3$ ,  $\text{NO}_2$  and  $\text{NH}_3$  emissions in China are necessary for a further mitigation of haze pollution in the country.

#### CRediT authorship contribution statement

GW conceived the experiment. SZ, DL and SG performed the experiment. GW, SZ and SG conducted the data interpretation and wrote the paper. SL, YW, CW, SL, FW and YC contributed useful discussions and comments.
