Quantitative Performance Evaluation of Uncertainty-Aware Hybrid AADL Designs Using Statistical Model Checking

Yongxiang Bao, Mingsong Chen* Member, IEEE, Qi Zhu Member, IEEE, Tongquan Wei Member, IEEE, Frederic Mallet Member, IEEE and Tingliang Zhou

Abstract—Hybrid Architecture Analysis and Design Language (AADL) has been proposed to model the interactions between embedded control systems and continuous physical environment. However, the worst-case performance analysis of Hybrid AADL designs often leads to overly pessimistic estimations, and is not suitable for accurate reasoning about overall system performance, in particular when the system closely interacts with an uncertain external environment. To address this challenge, this paper proposes a statistical model checking based framework that can perform quantitative evaluation of uncertainty-aware Hybrid AADL designs against various performance queries. Our approach extends Hybrid AADL to support the modeling of environment uncertainties. Furthermore, we propose a set of transformation rules that can automatically translate AADL designs together with designers’ requirements into Networks of Priced Timed Automata (NPTA) and performance queries, respectively. Comprehensive experimental results on the Movement Authority (MA) scenario of Chinese Train Control System Level 3 (CTCS-3) demonstrate the effectiveness of our approach.

Index Terms—Hybrid AADL, Uncertainty, Statistical model checking, Quantitative performance evaluation.

I. INTRODUCTION

Today promptly and accurately sense and control the physical world, more and more real-time embedded systems are deployed into our surrounding environment. As a result, the stringent safety-critical requirements coupled with increasing interactions with uncertain physical environments make the design complexity of Cyber-Physical Systems (CPS) skyrocketing [1], [2]. Unfortunately, due to the lack of architecture-level performance evaluation approaches considering uncertain environments, the required performance of integrated CPS implementations can be easily violated. Therefore, how to model the uncertain behaviors of both cyber and physical elements and how to guarantee meeting the critical functional and real-time requirements have become major challenges in CPS architecture design.

Architecture Analysis and Design Language (AADL) [3], [4], [5] has been widely adopted for the design and analysis of safety-critical real-time systems (e.g., automotive, avionics and railway systems). By defining various modeling constructs for hardware and software components, AADL core language supports the structural description of system partitioning and connectivity among components, while the semantics of AADL can be extended via annex sublanguages and user-defined properties. An AADL specification provides a set of modeling constructs for the description and verification of both functional and non-functional properties of interacting software and hardware components. Since the core AADL language only supports modeling of hardware and software components, to model the physical environment we adopt the Hybrid AADL, which supports continuous behavior modeling via the Hybrid annex [6].

When modeling a safety-critical system using AADL, before the design refinement, there is a rigorous certification process to verify whether the AADL design satisfies the required safety properties. Although existing AADL IDE tools such as OSATE [7] can be used to check timing properties (e.g., flow latency), most of existing approaches adopt the worst-case timing analysis without considering performance variations, which can easily lead to overly pessimistic performance estimations. To extend the performance analysis capability of AADL designs, various model transformation approaches [8], [9] have been proposed to verify AADL models based on existing verification and analysis tools. For quantitative analysis of AADL designs with uncertain environment, designers would like to ask questions such as “What is the probability that a specified scenario can be achieved within time x?” However, existing approaches focus on checking safety properties that only have an answer of “yes” or “no” without considering uncertain environments. Few of them can quantitatively reason why a given performance requirement cannot be achieved and answer how to improve the design performance. Clearly, the bottleneck is the lack of powerful quantitative evaluation approaches that can help AADL designers to make decisions during the architecture design.

To enable the quantitative analysis for Hybrid AADL designs, we propose a novel framework based on Statistical Model Checking (SMC) [10] which relies on the monitoring of random simulation runs of systems. By analyzing the simulation results using statistical approaches (e.g., sequential hypothesis testing or Monte Carlo simulation), the satisfaction probability of specified properties (i.e., performance requirements) can be estimated. Unlike traditional formal verification methods, which need to explore all the state space, SMC only investigates a limited number of simulation runs of systems and requires far less memory and time. Therefore, SMC is
very suitable for the approximate functional validation of complex AADL designs. We use the statistical model checker UPPAAL-SMC [10] as the engine of our approach, to leverage its rich modeling constructs and flexible mapping mechanisms.

Based on UPPAAL-SMC, this paper makes three following major contributions: i) We extend the syntax and semantics of Hybrid AADL specifications [6] using our proposed Uncertainty annex, which enables the accurate modeling of both performance variations caused by uncertain environments and performance requirements specified by designers. ii) To automate the quantitative analysis of uncertainty-aware Hybrid AADL designs, we rely on Network of Priced Timed Automata (NPTA) [10] as the model of computation in our approach. We propose a set of mapping rules that can automatically transform uncertain-aware Hybrid AADL designs into NPTA models and convert the performance requirements into various kinds of queries in the form of cost-constrained temporal logic [11]. iii) Based on our proposed SMC-based evaluation framework, we implement a tool chain that integrates both UPPAAL-SMC and the open-source AADL tool environment OSA TE to enable the automated performance evaluation and comparison of uncertainty-aware Hybrid AADL designs.

The rest of this paper is organized as follows. After introducing the related work on AADL and SMC-based evaluation approaches in Section II, Section II presents the details of our proposal. Based on an industrial CTCS-3 MA design, Section IV shows that our proposed approach can be effectively applied to the quantitative analysis of Uncertain Hybrid AADL designs. Finally, Section V concludes the paper.

II. RELATED WORK

To facilitate architecture design and analysis of safety-critical systems, various AADL simulation and verification tools were investigated [5]. For example, Jahier et al. [15] proposed an approach that can translate both AADL models and software components developed in synchronous languages (i.e., SCADE, Lustre) into executable models, which can be simulated and validated together. In [13], Yu et al. presented a co-simulation and co-verification framework for AADL and Simulink designs. Based on a formal polychronous/multi-clock model of computation, an original clock-based timing analysis and validation of the overall system is achieved. In [16], Larson et al. introduced the Behavioral Language for Embedded Systems with Software (BLESS) annex for AADL. The extended AADL language enables engineers to specify contracts on AADL components that can capture both functional and timing properties. They also developed the BLESS proof tool which can check whether AADL behavioral descriptions conform to specified contracts. Although these approaches are promising in functional checking, few of them consider performance issues for AADL designs.

Rather than developing dedicated verification tools for AADL designs, more and more model transformation-based AADL analysis approaches resort to the benefits of widely-used model checking techniques [18]. For instance, Hu et al. [8] presented a set of formally defined rules that can translate a subset of AADL to corresponding Timed Abstract State Machines (TASM) models for the purpose of timing and resource verification. To ensure completeness and consistency of an AADL specification as well as its conformity with the end product, Johnsen et al. [9] presented a formal verification technique by translating AADL designs to timed automata models. In [12], Bozzano et al. proposed a formal semantics for AADL that incorporates functional, probabilistic and hybrid aspects. Based on model checking techniques, they developed a toolset that can be used for a wide spectrum of design purposes ranging from requirements validation to performability evaluation and diagnosability analysis. Although the above model checking-based methods can check the functional correctness of systems in a fully automated manner, most of them suffer from the state space explosion problem [18]. Moreover, very few of them take the uncertain physical environment into account.

Since cyber-physical systems interact with surrounding physical environment frequently, the behavior modeling and verification of multirate and hybrid systems have become important research topics in AADL design. For example, Bae et al. [14] proposed a modeling language named Multirate Synchronous AADL, which can be used to specify multirate synchronous designs using existing AADL modeling standard. They also defined the formal semantics of Multirate Synchronous AADL, which enables the formal verification using Real-Time Maude. Based on BLESS annex [16] and Hybrid annex [6], Ahmad et al. [20] modeled and analyzed the movement authority scenario of the Chinese Train Control System Level 3 (CTCS-3) in AADL. Their approach can verify both discrete and hybrid behaviors of annotated Hybrid AADL designs based on the interactive Hybrid Hoare Logic theorem prover [17]. However, since their approach is based on theorem proving methods, it cannot be fully automated due to the required expert knowledge and manual “proof assistants”. Furthermore, existing theorem proving based methods focus on proving functional correctness of AADL designs. Few of them can be used to evaluate design performance within uncertain physical environment.

Due to its scalability and effectiveness in evaluating stochastic behavior, statistical model checking has become a preferred option in performance analysis of system designs with uncertainties [21]. Since statistical model checking is based on simulation, it requires far less memory and time, which enables highly scalable validation for AADL designs. For example, Bruinjes et al. [24] introduced a statistical model checking approach for timed reachability analysis of extended AADL designs. They developed a simulator that can perform probabilistic analysis of underlying stochastic models using Monte Carlo simulation. Our approach differs greatly from [24]. In [24], the extended AADL is based on linear-hybrid models, whereas our approach supports the modeling of nonlinear behaviors for a large group of CPSs. In particular, the clock rates in UPPAAL-SMC can be described using ordinary differential equations [10], e.g., \( c_1' = \sin(c_2) \), \( c_1' = c_1 \cdot c_2 + c_3 \), where \( c_1 \), \( c_2 \) and \( c_3 \) are three clock variables. In addition to the capability of modeling nonlinear behaviors, our approach focuses on evaluating CPS performance under uncertain environments, while [24] emphasizes on the error behavior modeling of hardware.
and software components. Moreover, [24] only considers the probability of event occurrences and delay variations following either uniform or exponential distributions, while our approach allows designers to define their own uncertain objects (e.g., system parameters, user inputs) following a wide spectrum of programmable distributions. Furthermore, the method in [24] only supports the evaluation of time-bounded queries, while our evaluation approach is based on cost-constrained temporal logic which is more comprehensive.

To the best of our knowledge, so far there is no approach that supports the performance evaluation for Hybrid AADL designs considering the uncertainties caused by physical environments. Our proposed approach is the first attempt that not only supports the uncertainty modeling in AADL, but also enables the quantitative performance reasoning and comparison of uncertainty-aware designs at the architecture level.

III. OUR APPROACH

Figure 1 shows the workflow of our approach. Since the core AADL focuses on structural modeling, to describe concrete execution behaviors of components, we need to resort to annex modeling which is a mechanism provided by AADL for the purpose of semantics extension. In this paper, we focus on uncertain hybrid systems, thus our approach adopts the Hybrid and BLESS annexes to describe the dynamic and hybrid behaviors of systems. To extend the semantics of hybrid systems, we propose the Uncertainty annex to specify various performance variations (e.g., network delays, sensor inputs) and performance requirements posed by designers. Based on our defined AADL and NPTA meta-models, Hybrid AADL designs with extended performance variation information can be extracted and transformed into corresponding uncertainty-aware NPTA models. The specified performance requirements are also parsed by our developed parser for the generation of properties, which are in the form of cost-constrained temporal logic [10]. Based on statistical model checker UPPAAL-SMC, our approach can conduct the quantitative evaluation of Uncertain Hybrid AADL designs against various properties (i.e., performance and safety queries). In the following subsections, we explain the major steps of our approach in details.

A. Uncertainty-Aware Modeling of Hybrid AADL

To model a hierarchical real-time system, a typical AADL [3], [4] design comprises both software components and their corresponding execution platform. Software components such as thread, thread group, process, data and subprogram can be used to construct the software architecture of systems. Execution platform components including processor, memory, device and bus can be used for hardware modeling. Within a system, all these components communicate with each other through connections to accomplish specific functions.

Definition 3.1: An Uncertain Hybrid AADL design is a 9-tuple \(<Comp, P_{ort}, C_{conn}, M_{p}, D, \Sigma, M_{a}, A_{annex}, M_{a} >\) where: i) Comp is a finite set of hardware/software components including their declarations and implementations; ii) \(P_{ort}\) is a finite set of component ports including data ports, event ports and event data ports; iii) \(C_{conn}\subseteq P_{ort} \times P_{ort}\) denotes a finite set of connections between ports; iv) \(M_{p}: P_{ort} \rightarrow Comp\) assigns ports to corresponding components; v) \(D\) is a finite set of data which can be transferred via connections; vi) \(\Sigma\) is a finite set of AADL properties; vii) \(M_{a}: \Sigma \rightarrow Comp\) assigns AADL properties to corresponding components; viii) \(A_{annex}\) is a finite set of annex declarations, i.e., BLESS annex, Hybrid annex, and Uncertainty annex; ix) \(M_{a}: A_{annex} \rightarrow Comp\) maps annexes to their components.

To enable the quantitative evaluation of Hybrid AADL designs considering uncertain environments, Definition 3.1 gives the formal definition of our Uncertain Hybrid AADL. In AADL, the definitions of both hardware and software components contain two parts, i.e., declaration and implementation. To enable interactions with other components, declaration defines ports for components which can be used to transmit and receive data or events, whereas implementation provides the details of a component including its subcomponents, properties and the connections between ports. In addition to basic data types, AADL allows designers to define their own data types to enrich AADL designs.

By using annexes, designers can precisely define and interpret behaviors of components by themselves. Different from traditional AADL designs, our Uncertain Hybrid AADL is based on a combination of BLESS, Hybrid and Uncertainty
annex declarations. Our approach adopts BLESS annexes and Hybrid annexes to model the discrete and continuous behaviors of AADL components, respectively. To model various uncertainties caused by external environment, we introduce the Uncertainty annex.

1) Background of BLESS and Hybrid Annexes: Based on state machine like semantics, BLESS annex [16] provides a set of notations which can be used to formally define discrete component behaviors, while the BLESS assertions can be used to specify and check the desired system properties. Definition 3.2 gives the formal definition of a BLESS Annex Instance (BAI) which can be embedded into a component implementation. Note that a transition of a BAI may have multiple actions for variable assignments or port communications. Since our approach does not adopt the assertions provided by BLESS annex, we did not incorporate it in Definition 3.2.

**Definition 3.2:** A BLESS Annex Instance [16] is a 6-tuple \( < S, G, Act, T > \) where, i) \( S \) is a finite set of states; ii) \( G \) is the initial state; iii) \( Act \) is a finite set of functions; iv) \( T \) is a finite set of guard conditions over \( BV \); and v) \( T \subseteq S \times G \times 2^{Act} \times S \) denotes the definite set of transitions.

Definition 3.3 gives the formal definition of Hybrid annex instances. Based on semantics of Hybrid CSP (Communicating Sequential Processes) [6], [27], Hybrid annex can be applied in continuous behavior modeling of AADL device and abstract component implementations, such as sensors, actuators and physical processes. When using the Hybrid annex, both discrete and continuous variables are declared in the *variables* section, and the values of constants are initialized in the *constants* section. The *behavior* section of a Hybrid Annex Instance (HAI) is used to describe the continuous behaviors of annotated AADL components in terms of concurrently-executing processes. Such behaviors indicating continuous process evolutions are specified using differential expressions. The physical processes communicate with each other using channels (declared in the *channels* section) or ports (i.e., the ports of associated AADL component). Continuous process evolution may be terminated after a specific time or on a communication event, which is invoked through timed and communication interrupts, respectively. A timed interrupt preempts continuous evolution after a given amount of time. A communication interrupt preempts continuous evolution whenever communication takes place along any one of the named channels or ports. For more details of the processes and interrupts, please check the examples shown in Listing 1 and the model transformation rules in Section III-B5. Note that the Hybrid annex also supports assertions which take the same format as BLESS assertions [16]. Since none of these assertions are suitable for quantitative analysis, we neglect the assertion definition in Definition 3.3.

**Definition 3.3:** A Hybrid Annex Instance is a 6-tuple \( < HV, HC, P, CP, I, M_t > \) where, i) \( HV \) is a finite set of discrete and continuous variables; ii) \( HC \) is a finite set of constants that can only be initialized at declaration; iii) \( P \) is a finite set of processes that are used to specify continuous behaviors of AADL components; iv) \( CP \) is a finite set of channels and ports for synchronizing processes; v) \( I \) is a finite set of time or communication interrupts; and vi) \( M_t : I \rightarrow P \) binds interrupts to associated processes.

2) Definition, Syntax and Semantics of Uncertainty Annex: Although there are many tools that are proposed to check the performance of AADL designs, most of them assume a uniform distribution for flow delays. Few of them consider the variations (e.g., sensor inputs, network delays) caused by uncertain environments. To support the modeling of such kinds of uncertainties, based on Definition 3.4, we extend the semantics and syntax of Hybrid AADL using our proposed Uncertainty annex.

**Definition 3.4:** An Uncertainty Annex Instance (UAI) is a 7-tuple \( < TV, PV, DIST, M_{tv}, M_{pv}, M_{dist}, Q > \) where, i) \( TV \) is a finite set of stochastic time variables; ii) \( PV \) is a finite set of stochastic price variables; iii) \( DIST \) is a finite set of distribution functions; iv) \( M_{tv} : TV \rightarrow \{ P_{ort} \cup T \} \) binds each time variable \( tv \in TV \) to a port \( p \in P_{ort} \) or a transition \( t \in T \); v) \( M_{pv} : PV \rightarrow \{ BV \cup HC \} \) binds each variable \( pv \in PV \) to a variable \( bv \in BV \) or a constant \( hc \in HC \); vi) \( M_{dist} : \{ TV \cup PV \} \rightarrow DIST \) assigns each variable \( v \) with a distribution function; and vii) \( Q \) is a finite set of queries for the quantitative performance evaluation.

Unlike existing approaches, our Uncertainty annex supports a large spectrum of distributions which can be used to accurately capture the system behaviors within an uncertain environment. To simplify the stochastic behavior modeling, we define two kinds of stochastic variables, i.e., *time variables* which denote the time variations of AADL constructs (e.g., ports), and *price variables* which indicate the value variations of AADL variables and constants. For example, if a time variable \( tv \) is bound to a port \( p \), the data transmission time via \( p \) follows the specified time distribution \( M_{dist}(tv) \). Note that Uncertainty annex itself is only a syntactical notation, which specifies the uncertain values for constants and variables and uncertain communication delays for ports. It does not change the semantics of Hybrid AADL designs. To enable the statistical model checking, the Uncertainty annexes are used to indicate the value of constants/variables or the delay of ports at the beginning or during the execution of a simulation run following the give distributions. During the automated quantitative evaluation, Uncertainty annex allows the designers to specify their queries to assess whether an Uncertain Hybrid AADL design satisfies the requirements.

\[
\text{Uncertainty Annex} ::= \{ \text{variables} \{ \text{variables} \text{Declaration} \} + \text{distributions} \{ \text{distribution} \text{Declaration} \} + \text{queries} \{ \text{query} \text{Declaration} \} + \}
\]

As an extension, UAI can be embedded into AADL components as a subclause to specify their uncertain behaviors. To describe the context-free syntax of UA, we explain all the notations of Uncertainty annex using the Extended Backus-Naur Form, where literals are printed in bold; alternatives are separated by “|”; grouping are enclosed with parentheses”.( )”;
square braces "[ ]" delimit optional elements; and "{ }+" and "{ }∗" are used to signify one-or-more, and zero-or-more of the enclosed elements, respectively. As shown in the above production rule, an Uncertainty annex consists of three parts, i.e., variables section, distributions section and queries section. Their functions and usages are explained as follows.

**Variables section:** Instead of modeling the uncertainties of environment components directly, our approach implicitly reflects the environment uncertainties by specifying distributions for both data transmission time via connections between interconnected ports and the values of system parameters (e.g., AADL variables and constants). To model stochastic behaviors of systems, we define local variables in this section to indicate the uncertain dynamics of the corresponding AADL component features. In our approach, all these variables are associated with specific probability distributions to signify their possible values within an uncertain environment. The following rules show the grammar for variables section.

```plaintext
variables_declaration ::= 
  type_prefix {variable_identifier}+ 
  applied to {component_ref}+

type_prefix ::= time | dynamic price | static price

component_ref ::= features_ref | annex_subclause
```

In the above rules, the type prefix time means that local variables are used to model the stochastic timing information of component features. For example, a local time variable can be bound to a component port to specify uncertain communication delays on the connection via this port. The local variables with type prefix static/dynamic price can be used to specify the uncertain value assignment for variables and constants declared in annotated components or their annexes. In our approach, we consider two kinds of local price variables, i.e., static price variables and dynamic price variables. Here, static price means that the initial value of the associated AADL (or annex) variables and constants are assigned stochastically at the beginning of system execution. Unlike static price variables which only conduct the initialization of variables or constants once, local dynamic price variables are usually bound to AADL (or annex) variables to model their random value updates when newly referred.

**Distributions section:** The distributions section is to specify the probability distributions of the variables defined in the variables section. To allow the modeling of various stochastic behaviors, our Uncertainty annex has a built-in distribution functional library that supports a large spectrum of widely used distributions, such as uniform, exponential and normal distributions. The following production rules show how to bind a variable with a specific distribution function.

```plaintext
distribution_declaration ::= 
  variable_identifier_reference = distribution

distribution ::= Normal(‘const,const’) | Uniform(‘const,const’) | Exponential(‘const’) | ...
```

**Queries section:** To quantify the performance of Uncertain Hybrid AADL models during the architecture level design, designers would like to ask questions such as “what is the probability that a scenario can happen or a condition can be satisfied with limited resources?”. Uncertainty annex provides the queries section that can be used for declaring such queries to enable safety and performance evaluation of AADL designs. As an effective way to check the quality and performance of AADL designs, the designers can put their design requirements in this section. Only when all the evaluated requirements meet design targets, the AADL design can be used as a reference for the implementation.

```plaintext
query_declaration ::= 
  query_identifier = query_target under constraint 
  query_target ::= expr \{\&\& expr\}*

expr ::= condition \{‘( condition \&\& || expr ‘)’

condition ::= identifier operation (const | identifier) 

constraint ::= identifier | operation const

operation ::= < | ≤ | == | != | ≥ | >
```

When specifying a query, designers should provide two things: i) a query target that denotes a safety scenario or performance metric in the form of a predicate expression; and ii) a constraint indicating the available resources to achieve the target. The above production rules present how to declare queries. Here, identifier denotes the name of AADL features (e.g., ports) or annex variables declared in annotated component implementations, and const denotes a constant value. The target of a query is a predicate represented by a conjunction of expressions. The query constraint is in the form of “res op lim”, where res, op and lim denote resource, operation and resource limit, respectively. If the resource is not specified explicitly, the system time will be used as the resource by default.

Listing 1 presents a Hybrid AADL design example annotated with an uncertainty annex instance, which describes the uncertain behaviors of the train component within the CTCS-3 Movement Authority scenario (see details in Section IV). To operate safely, the train periodically sends its current location and velocity information to the on-board train controller through ports ts, tv and receives the acceleration instruction directed by the controller from the port ta. All these ports are defined in the Train declaration. To model the continuous behaviors, the train design adopts the Hybrid annex. Within the Hybrid annex, the system time is modeled using the continuous variable t whose rate is 1 (indicated by notation ‘DT 1 =1’ which means the derivation of t is 1). In the Hybrid annex behavior section, the notation ‘DT 1 s=ν’ defines train speed and the notation ‘DT 1 v=α + f r’ denotes the acceleration of the train. During the running, the traction control force is determined by the value of a calculated by the controller, while the resistance is determined by the friction coefficient of the track. In this example, we consider two kinds of uncertainties. The first one represents uncertain communication delays between trains and controllers. The second one is the track friction which is highly dependent on the external environment (e.g.,
weather, temperature). Therefore, we define two local variables in the variables section of the uncertainty annex. The time variable \(v_{\text{delay}}\) is bound to the port \(ts\) with a distribution \(\text{Normal}(0.15,0.04)\) (defined in the distributions section). We set the variable \(v_{\text{fr}}\) as a static price variable, since we assume that the coefficient for the whole track and its value is only updated once at the beginning of each system run. In the queries section, query \(p1\) tries to figure out the probability that the train can stop before the end of authority (denoted by \(\text{EOA}\)) within 300 seconds, and query \(p2\) tries to reason whether the train can run 4 kilometers within 200 seconds.

**B. NPTA Generation from Uncertain Hybrid AADL**

To formalize the semantics of Uncertain Hybrid AADL, we adopt NPTA as the model of computation. This subsection presents our model transformation approach in detail.

1) Preliminary Knowledge of NPTA: Unlike traditional timed automata, the clocks of a Priced Timed Automaton (PTA) [25] can evolve with different rates. To simplify the formal definition, we skip the introduction to the richer flavors of PTAs supported by UPPAAL-SMC, e.g., urgent locations [25]. Let \(C\) be a clock set. A clock valuation is a function \(v: C\rightarrow R_{>0}\) which maps \(C\) to the set of non-negative reals \(R_{>0}\). Let \(v_0\) be the initial valuation where \(v_0(c) = 0\) for all \(c\in C\). Let \(\mathcal{U}(C)\) (\(\mathcal{L}(C)\)) be the set of upper-bound (lower-bound) guards which are in the form \(x\sim k\) or \(x-y\sim k\), where \(x,y\in C, k\in R\) and \(\sim\in\{<,\leq,==\}\) (\(\sim\in\{>,\geq,==\}\)). Assuming \(g\in\mathcal{L}(C)\cup\mathcal{U}(C), v(C)\models g\) denotes that valuation \(v(C)\) satisfies the constraint \(g\). Definition 3.5 presents the formal definition of a PTA.

### Definition 3.5: A PTA is a 8-tuple \(A = (L,l_0,C,\Sigma,E,R,I,\tau)\) where:
- \(L\) is a finite set of locations;
- \(l_0\in L\) is the initial location;
- \(C\) is a finite set of clocks;
- \(\Sigma = \Sigma_0\cup\Sigma_a\) is a finite set of actions where \(\Sigma_0\) and \(\Sigma_a\) indicate exclusive input actions and output actions, respectively;
- \(E\subseteq L\times\mathcal{L}(C)\times\mathcal{U}(C)\times\mathcal{X}^C\times L\) is a finite set of transitions, where \(\mathcal{L}(C)\) denotes the transition guard and \(\mathcal{X}^C\) denotes a set of reset clocks of the transition; and
- \(R: L\rightarrow\mathcal{U}(C)\) assigns a clock rate vector to each location, where \(R(c)\) specifies the clock rate for \(c\in C\) in the form of ordinary differential equations; and
- \(I: L\rightarrow\mathcal{U}(C)\) assigns an invariant to each location; and
- \(\tau\) is the system clock which is never reset.

Let \(A_1 = (L_1,l_0',C_1,\Sigma_1,E_1,R_1,I_1,\tau)\) and \(A_j = (L_j,l_0',C_j,\Sigma_j,E_j,R_j,I_j,\tau)\) \((i\neq j)\) be two PTAs. The PTAs \(A_1\) and \(A_j\) are composable into a network only if \(C\cap C_j = \emptyset\) and \(\Sigma_0\cap\Sigma_0' = \emptyset\).

### Definition 3.6: Let \(A_j = (L_j,l_0',C_j,\Sigma_j,E_j,R_j,I_j,\tau)\) \(1\leq i\leq n\) be a PTA. Their composition \((A_1...A_n)\) is an NPTA which is a 8-tuple \(NA = (NL,NL_0,NC,NS,NE,SR,NI,\theta)\), where:
- \(NL\) is a clock set \(L_j\);
- \(NL_0 = x_j(L_j)\); and
- \(NC\) includes \(C_j\); and
- \(NS = \cup_j\Sigma_j\), \(NE = \cup_j\Sigma_j\), \(SR = \cup_j\Sigma_j\), \(NI = \cup_j\Sigma_j\), \(\theta\) is a function \(\theta_1\).

2) An Example of NPTA with Uncertainties: Figure 2 shows an NPTA consisting of two PTAs \(A\) and \(B\), where each PTA has four locations and two clocks (e.g., \(c_1\) and \(c_u\) in \(A\)). The locations here marked with symbol “U” are urgent locations which can freeze time. In other words, time is not allowed to pass when a PTA is in an urgent location [10]. Note that clocks can evolve with different rates in different

![Fig. 2. An NPTA (AB)](image-url)
locations. The rate of a clock is 1 by default. To change the rate of a clock, we need to modify the rate value of the primed version of the clock. For example, \(c_1' = 3\) in \(A_2\) denotes that the rate of \(c_1\) is 3 in this location. Since UPPAAL-SMC supports the modeling of clock rates using expressions in the form of ordinary differential equations, UPPAAL-SMC can be used to model non-linear hybrid systems. Note that although UPPAAL-SMC only supports the uniform and exponential distributions explicitly, based on the C-like programming constructs and built-in function random() provided by UPPAAL-SMC various distributions can be constructed. For example, we can construct the normal distribution based on the Box-Muller approach [19]. Assume that the values of two variables \(t_1\) and \(t_2\) follow the normal distributions \(N(1,0,3^2)\) and \(N(4,1^2)\), respectively. The action \(t_1=\text{Normal}(1,0,3)\) on the outgoing edge of \(A_1\) assigns \(t_1\) with a random value following \(N(1,0,3^2)\). Since the invariant in \(A_2\) is \(c_1 \leq t_1\) and the guard on the outgoing edge of \(A_2\) is \(c_1 \geq t_1\), PTA \(A\) is stuck at \(A_2\) for a time of \(t_1\). If the NPTA is simulated for numerous times, the sojourn time at location \(A_2\) follows the distribution \(N(1,0,3^2)\).

In this example, PTAs are synchronized by two complementary action pairs (“!” indicating sending and “?” denotes receiving) via urgent channels \(a\) and \(b\). While simulating \((A/B)\) with a large number of runs, we can find that the reaching time of the composite location \((A_3, B_3)\) follows the normal distribution \(N(4+1,1^2+0.3^2)\), since the sojourn time of \((A/B)\) at composite locations \((A_0, B_1)\) and \((A_2, B_2)\) follows the normal distributions \(N(4,1^2)\) and \(N(1,0,3^2)\), respectively. By adopting the NPTA template like the above example, arbitrarily complex stochastic behaviors can be modeled.

3) Mapping from Uncertain Hybrid AADL to NPTA: To facilitate the detailed modeling of system architectures, AADL provides more types of syntax modeling constructs than NPTA. Since our approach focuses on quantitative analysis of stochastic behaviors of Uncertain Hybrid AADL designs, during the model transformation we neglect all the AADL constructs which cannot affect the system behaviors. Table I shows the structural mappings from uncertain Hybrid AADL constructs to NPTA constructs. Note that we only list a subset of AADL constructs that have a strong correlation with uncertainty-aware hybrid features. This subset can essentially be used to fully describe the behaviors of hybrid systems within an uncertain environment. In our approach, we use the BLESS annex to specify the discrete components of systems, e.g., controller. We use the Hybrid annex to describe both discrete and continuous behaviors of hybrid components, e.g., plants. The instances of both annexes can be described using PTAs. Note that our proposed uncertainty annex focuses on the variation modeling of communication delays and parameter values. It only slightly changes structure of PTAs. To model the overall uncertain behaviors of the whole hybrid system, all the generated PTAs are synchronized through the channels, which are transformed from AADL connections. To guarantee the correctness of our mappings from AADL to NPTA and final translation results, we develop a comprehensive test suite which covers all possible notations of the three annexes. The testing results show that the NPTA generated by our transformation rules (templates) can correctly and accurately reflect the behaviors of Uncertain Hybrid AADL designs. In Section III-B5, we will show the details of such transformation rules with concrete examples.

Our approach relies on the meta-models of AADL and its annexes to guide AADL model parsing as well as the construct mapping. Similar to the formal definitions presented in Section III-A, the meta-models define a set of correlated sub-constructs of the model, which can be used to extract the necessary information for the model transformation. Due to the space limitation, we do not introduce the meta-models used in our approach here. The meta-model for the AADL without annex can be found in [4], and the meta-models for BLESS and Hybrid annexes can be obtained from [16] and [6], respectively. Similar to BLESS and Hybrid annex, the meta-model of Uncertainty annex can be inferred from Definition 3.4.

In our approach, the generated NPTA model can be divided into two parts: i) back-end configurations that are used to declare necessary data structures (e.g., variables, channels) and functions (e.g., distributions, actions) for the stochastic modeling of NPTA modes, and ii) front-end models that are used to model the behaviors of hardware, software and environment components. Our approach assigns each of AADL components annotated by BLESS and Hybrid annex subclauses with a front-end model and a back-end configuration. Moreover, there is a global back-end configuration for the whole system whose information are shared by all the front-end models.

4) Back-end Configuration Generation: As a textual file, a back-end configuration mainly consists of: i) a set of declarations of variable and channels, and ii) a set of distribution and action functions. By using our approach, such information can be automatically extracted from AADL designs. Listing 2 shows the back-end configuration generated from the train AADL shown in Listing 1. To save the space, we put both the global configuration and the local configuration for the train within the same file.

For a back-end configuration, the global declarations of variable and channels are generated from the top level of AADL designs, i.e., hardware/software components and their interconnections. For each port of an AADL component, we create an urgent channel which indicates the AADL connection associated with the port. For example, assuming that the connection name bound by the port \(tv\) in the AADL

\begin{table}[h]

Hybrid annex subclause & PTA template \\
Uncertainty annex subclause & PTA actions/invariants/guards \\
\hline
\end{tabular}
\caption{Construct Mappings between AADL and NPTA}
\end{table}

\footnote{An urgent channel does not allow a delay if it is possible to trigger a synchronization over it. We only use urgent channels in our translation, since the timing behavior of NPTA using urgent channels is deterministic. We use urgent locations in the transformation for the same reason.}
**Uncertainty Modeling of Front-end Model:** For front-end model transformation, we consider two kinds of uncertainties in the Uncertainty annex. The first one is described by time variables which are used to model the delay variations of network communication or task execution. To model such stochastic timing behaviors of system, we use the transformation pattern as shown in Figure 3. Figure 3(a) shows a scenario that the PTA tries to send something via the channel using the action channel!. Without annotated Uncertainty annexes, the sending time of the action is fixed. However, by using our Uncertainty annex, we can associate a time variable \( v_{delay} \) following normal distribution (i.e., \( N(1,0.2^2) \)) with this channel. By splitting the transition in Figure 3(a) and introducing a temporary location to indicate the waiting, we can model the scenario that the action time follows the distribution \( N(1,0.2^2) \) as shown in Figure 3(b). On the incoming edge of the newly added location \( temp \), we assign \( v_{delay} \) with a random value following \( N(1,0.2^2) \) and we reset the clock \( d_{fr} \). Note that the invariant of location \( temp \) is \( d_{fr} = v_{delay} \) and the guard on the outgoing edge of \( temp \) is \( d_{fr} = v_{delay} \). Therefore, the PTA remains at location \( temp \) for a time of \( v_{delay} \) following the normal distribution \( N(1,0.2^2) \).

The second uncertainty in the front-end model is specified by dynamic price variables in the Uncertainty annex, which mimics the random values of parameters (e.g., sensor inputs). The transformation of such uncertainty only needs to assign or replace the applied variable with the given distribution function.

---

**BLESS Annex Based PTA Generation:** Listing 3 presents an AADL example annotated with both BLESS and Uncertainty annex instances, which describes the uncertain behaviors of the controller component within the CTCS-3 Movement Authority scenario (see details in Section IV). Meanwhile, Figure 4 shows the corresponding PTA generated using our transformation rules. Due to the space limitation, we only give the partial AADL specification and corresponding PTA for the controller.

---

Listing 2. Back-end configuration of *Train*

The local back-end configuration mainly deals with the definition of data structures for specific AADL components and annexes. During the model transformation, all the continuous AADL variables are converted to clock typed variables, and other AADL variables are converted to non-clock variables with different types. For each local configuration of PTAs, we define one built-in function \( initialize() \) which is used to initialize the values of variables. To enable the reset operation in a PTA, for each local configuration, we define one clock \( d_{fr} \). For the uncertainty annex in Listing 1, there are two variables declared, i.e., \( v_{delay} \) and \( v_{fr} \). Note that only \( v_{delay} \) has a counterpart in the back-end configuration, since it is a time variable. The price variables have no counterparts, since they are used as intermediate variables during the model transformation. Note that the transformation rules for static and dynamic price variables are different. Since static price variables only take effect at the beginning of the simulation, we assign their random values to associated variables in the function \( initialize() \) of local back-end configurations. For example, we initialize the variable \( fr \) with a value following normal distribution \( N(-0.1,0.05^2) \) in the back-end function \( initialize() \) of the train example. Unlike static price variables, the dynamic price variables generate random values during the execution when necessary. It is widely used in front-end modeling to indicate the random value change of variables. For example, it can be used to model time-varying port delays.

5) Front-end Model Generation: As a graphical representation, front-end models are used in UPPAAL-SMC to describe the stochastic behaviors of PTAs. To describe the hybrid behaviors of systems, our approach adopts two kinds of annexes. We model the discrete behaviors of AADL components (e.g., thread component) using the BLESS annex. To describe continuous behaviors of components (e.g., device and abstract components), we use the Hybrid annex that is based on Hybrid CSP. For an AADL component without any annotated annexes, we assume a simplified semantics for its behavior, where the component periodically receives the data from its input ports and sends the data to its output ports. Therefore, the major task of front-end model generation is to transform uncertainty-aware BLESS and Hybrid annexes to their NPTA counterparts.

continuous evolution after an amount of time (i.e., \(time_val\)). By using the similar transformation pattern shown in Figure 3, we can assure that the continuous evolution of CSP process can be interrupted after a time of \(time_val\). The communication interrupts enable the preemption of continuous evolutions by communication events via AADL ports. For example, the communication interrupt in the form of \([>\text{pout}!(v)]\) \(\Rightarrow EV\) denotes that whenever a value of \(v\) is sent out the port \(\text{pout}\), the current evolution will be terminated and the CSP process \(EV\) will be adopted as the subsequent behavior of the process.

Generally, a communication interrupt may contain a sequence of send or receive actions. During the PTA transformation, we model the actions based on their occurrence order in the interrupt. For each action, we generate a new PTA location together with a new transition with the corresponding action on it. Note that in the generated PTA a location should be set as urgent if the action on next edge is a send action. When translating the \(\text{choice}\) operator of a CSP process, we will create a new adjacent location in the generated PTA for each alternative. The subsequent behavior of the process is determined by the Boolean expression associated with the alternative. To model the behavior of a repeating process defined in the behavior section, we connect the last location to the first location of the process in the PTA to form a loop.

C. Property Generation for Quantitative Analysis

To enable the quantitative evaluation of Uncertain Hybrid AADL designs, our proposed Uncertainty annex allows designers to specify design requirements as performance queries. These performance queries will be transformed as properties in the form of cost-constrained temporal logic to reason the performance of the NPTA models generated from Uncertain Hybrid AADL designs. Since we focus on the reasoning of stochastic behaviors of AADL systems, the designers can conduct following two kinds of queries.

- **Performance query**: The performance query can be used to check the probability that an expected performance metric can be achieved under a given resource limit. The performance metric can be expressed as the predicate and the resource limit can be specified as the constraint using the keyword \(\text{under}\).

- **Safety query**: The safety query can be used to check the probability that an unexpected scenario can happen eventually with a given resource limit. In the query, the unexpected scenario can be expressed as the predicate and the resource limit can be specified as the constraint using the keyword \(\text{under}\).

Although safety queries and performance queries have different meaning, they share the same template during the property generation. In the \(\text{queries}\) section, a query consists of two parts, i.e., predicate \(\phi\) and resource constraint \(\psi\). The predicate \(\phi\) can be used to denote either an unexpected scenario or an expected performance metric.

To evaluate the performance of generated NPTA models, UPPAAL-SMC adopts cost-constrained temporal logic [11] based performance queries in the form of \(\text{Pr}[^{\text{bound}}[^{<\text{expr}}]]\), where \([\text{bound}]\) indicates the bound of the cost and the expression \(<\text{expr}\) asserts that the scenario \(\text{expr}\) should happen eventually. By using our approach, the queries will be transformed into properties in the form of \(\text{Pr}[^{\psi}[^{<\phi}]]\). For example, the performance query \(p2\) in Listing 1 intends to check the probability that the travel length of the train exceeds 4 kilometers within 200 seconds. In order to conduct the quantitative evaluation using UPPAAL-SMC, the query will be converted to a property \(\text{Pr}[^{<\text{200}}[^{<\text{Train.ts}>=4000}]]\) in the form of cost-constrained temporal logic. Based on the specified probability of false negatives (i.e., \(\alpha\)) and probability uncertainty (i.e., \(\epsilon\)), UPPAAL-SMC will simulate a specific number of stochastic runs which are terminated when either \(\text{bound}\) or \(<\text{expr}\) holds. The success rate \(p\) of \(<\text{expr}\) satisfying \(\text{bound}\) will be reported in the form of a probability range \([p-\epsilon,p+\epsilon]\) with a specified confidence \(1-\alpha\).

IV. Case Study

To show the efficacy of our approach in analyzing system performance within uncertain environments, this section
presents the experimental results of verifying the Movement Authority (MA) control of Chinese Train Control System Level 3 (CTCS-3) [20], [28]. By using our proposed Uncertainty annex, we extended the hybrid CTCS-3 AADL model presented in [20] using the tool OSATE2 [7]. The uncertainty information in the model is suggested by railway experts from our industrial partner Casco Signal Ltd. Based on our XMI parser and NPTA model generator implemented using JAVA, we can obtain the corresponding NPTA model as well as performance queries. We employed the model checker UPPAAL-SMC (version 4.1.19, α = 0.02, ε = 0.02) to conduct the evaluation. All the experimental results were obtained on a desktop with 3.3GHz AMD CPU and 12GB RAM.

A. System Model of CTCS-3 MA Scenario

As one of the fourteen basic scenarios of CTCS-3 System Requirements Specification (SRS), the MA control plays an important role in prohibiting trains from colliding with each other. Typically an MA scenario involves three major components as follows: i) trains that periodically (every 500 milliseconds) send their status information (i.e., current location and velocity) to the controller and receive acceleration information directed by the controller; ii) Radio Block Centers (RBCs) that provide MAs to trains based on information exchange with trackside subsystems and the on-board controller; and iii) on-board controller subsystems which control the velocity of trains by changing their accelerations.

![Fig. 6. MA scenario of CTCS-3 [20]](image)

As shown in Figure 6, the RBC assigns a dynamic MA to the left train based on the track situation and the movement of the right train. Here, EOA stands for the End of Authorization. When a train reaches a specific distance (i.e., SR) away from EOA, it needs to apply for a new MA. If the authorization is not granted in time, according to SRS the train should stop before the EOA. According to SRS [28], an MA comprises a sequence of segments, where each segment has two speed limits \( v_1 \) and \( v_2 \) (\( v_1 \geq v_2 \)). In this example, we set the speed limits \( v_1 \) and \( v_2 \) for each segment to 73m/s and 66m/s, respectively. If the train speed exceeds \( v_1 \) (\( v_2 \)), an emergency (normal) brake will be performed to slow down the train. Upon receiving an MA request from controller, RBC will reply with a new MA together with all the segment information (e.g., speed limits, operation mode). More details can be found in [20], [28]. In this example, we set the length of an MA to 6 kilometers, and set the length of SR to 1 kilometer. The train starts with a speed of 0m/s. All the segments have the same length and speed limits. Note that the SRS requirements cannot be guaranteed within an uncertain environment. For example, due to the mutual interference between varying communication delays and friction coefficient of tracks, inaccurate estimation of locations can make the train pass the EOA. Although train drivers can perform emergency brake manually, proper quantitative analysis of these unsafe scenarios should be studied at architecture level to make the train movement more safe.

![Fig. 7. AADL model for CTCS-3 MA](image)

Figure 7 shows the graphical AADL model for CTCS-3 MA design, where the controller plays a central role. Within the MA scenario, the controller sends the MA request to RBC via the port \( r \) and receives the segment and EOA information from the ports \( m \) and \( ea \), respectively. To achieve the train status, the controller receives the location and speed information from the ports \( cs \) and \( cv \) every 500 milliseconds. It also controls the train by specifying the newly calculated acceleration for the train via port \( ca \). Although this figure does not explicitly present any uncertainty information, in this example we consider various uncertainties that may affect the performance of the MA control, e.g., communication delays between RBC and controllers, computation time variations of both software/hardware components of controllers, and varied coefficient of friction of tracks. The cumulative variations by all these uncertainties strongly affect the performance and safety of the CTCS-3 MA. In other words, the risk of train collisions is high within an uncertain environment.

B. Uncertainties in CTCS-3 MA Scenario

As shown in Table II, this experiment took nine uncertain aspects of CTCS-3 MA into consideration. Similar to the work in [21], [26], this paper adopts normal distributions to model the performance variations in the CTCS-3 MA scenario. All such variation information was collected from historical data of train operations. Note that our approach supports a variety of distributions, which can be used to accurately model the Uncertain Hybrid AADL designs. In this table, the first column presents the category of the uncertainties. The second column presents the AADL constructs that cause the uncertainties. For example, when controller sends a MA request to RBC via port Controller.err, there is a delay variation caused by the connection conn_req following the distribution \( N(0.1, 0.03^2) \), where the expected execution time is 0.1 seconds and the standard deviation is 0.03 seconds. Note that during the statistical model checking the network delay of 0.1 seconds

---

2We have shared our tool (including the source code of Uncertain Hybrid AADL parser and NPTA model generator) and the uncertain CTCS-3 MA example on Github. The download address is https://github.com/tony11231/aadl2uppaal.
with standard deviation of 0.03 may lead to a negative value. In our approach, if the variable with type “time” is randomly assigned with a negative value, we will set it to 0. According to the three-sigma rule, this approximation will still be accurate in this case. The last two columns provide the variation distributions and value unit, respectively. By using our tool chain, the NPTA model of the Uncertain Hybrid AADL design can be obtained automatically.

**C. Performance Analysis for CTCS-3 MA Scenario**

To focus on quantitative analysis of the MA scenario influenced by uncertain factors, we investigated stochastic behaviors of a train within an MA as shown in Figure 6. We assume that the train will fail to get the next MA when entering SR. Therefore, it should stop before EOA. By using our tool, three queries are generated to analyze the performance of Uncertain Hybrid AADL design for CTCS-3 MA.

To investigate the probability that a train can stop safely before the end of authorization within 300 seconds, we adopt the performance query $Pr[<=300](<=Train.v<=0\&\&Train.s<=600\&\&Train.s>0)$, where $Train.v$ denotes velocity of the train and $Train.s$ indicates the location of the train. Figure 8 presents the evaluation results for the query in the form of Cumulative Probability Distribution (CPD). In this figure, the x-axis denotes the time limit, and the y-axis indicates success rate of the performance requirement indicated by the query. In this evaluation, we considered three Uncertain Hybrid AADL designs, where the accelerations directed by the controller are different. We set the accelerations of three designs to 0.3 MPSS (Meter Per Second Squared), 0.4 MPSS and 0.7 MPSS, respectively. By running 868 runs, we can get a probability interval [0.91,0.95] with a confidence 98% for the query of the AADL design with an acceleration of 0.3 MPSS. The SMC simulation for this query costs around 132 seconds. For the AADL designs with acceleration of 0.4 MPSS and 0.7 MPSS, we can get probability intervals [0.88,0.92] and [0.81,0.85] with a confidence of 98%, respectively. From this figure, we can find that the CPD of the design with 0.7 MPSS rises earlier (i.e., 173 seconds), since it has a larger acceleration and can reach the speed limit faster more quickly than the other two designs. However, the larger acceleration indicates the higher difficulty in managing the train speed. In other words, the chance that the train exceeds EOA becomes higher. Therefore, we can find that the AADL design with 0.3 MPSS can achieve the highest success rate to stop before reaching EOA. Moreover, we can find that the success rate will not increase significantly after a time threshold, since the train has stopped before the time limit, i.e., 300 seconds.

**Fig. 8. Performance query results with different accelerations**

The interaction frequency between trains and the controller plays an important role in CTCS-3 MA design, since it strongly affects the cost and performance of train designs. Although longer control periods cost less communication bandwidth, the infrequent updates of train accelerations make the train hard to be controlled. To investigate the effects of different control periods, we assume that the acceleration (without consider frictions) sent from the controller is fixed (i.e., 0.4 MPSS) for the train design. Figure 9 shows the evaluation results of using the same query as the one used in Figure 8. We consider three designs with different control periods, i.e., 0.2, 0.5 and 0.7 seconds, respectively. From this figure, we find that the design with the smallest control period (i.e., 0.2S) can achieve the highest rate of success. By running 266 runs, we can achieve a probability interval [0.95,0.99] with a confidence 98% for the query of the AADL design with a control period of 0.2 seconds.

**Fig. 9. Performance query results with different control periods**

To determine the performance of the AADL design, we used the query $Pr[<=200](<=Train.s>=4000)$ which checks whether the train can run a distance of 4.0 kilometers within 200 seconds. As shown in Figure 10, we adopted three designs with different accelerations. We can find that the performance difference among these three designs is quite small. The design with an acceleration of 0.3 MPSS achieves the worst performance, since it needs a worst-case time of 193 seconds to reach the specified location. Interestingly, the design with 1.0 MPSS does not win the comparison. It needs longer time to hit the specified location than the design with 0.6 MPSS, since the design with a larger acceleration will have a more drastic speed update near the speed limits.
From the above experimental results, we can find that our approach can be used to effectively reason about the performance of designs within complex uncertain environments. Our approach can not only support the qualitative evaluation of specified design using performance queries, but also can be used for the purpose of design optimization based on parameter tuning.

D. Quantitative Safety Analysis for CTCS-3 MA Scenario

During the running of the train, we expect the train speed not to exceed the upper speed limit \( v_1 \), since it can easily make the train derailed. Therefore, when the train reaches the speed \( v_1 \), we need to apply the urgent brake to reduce the train speed drastically. To check the probability of overspeed of trains, we used the safety query in the form of \( \text{Pr}[\text{Train} P_s \leq 5000] (<\text{Train} \ P_s > 73) \), which indicates that within a distance of \( EOA - SR \) the speed train cannot be larger than or equal to \( v_1 \) (i.e., \( 73 \text{m/s} \)).

\[ P(\text{Train} P_s < 5000 | (<\text{Train} \ P_s > 73)) \]

\[ P(\text{Train} P_s < 5000 | (<\text{Train} \ P_s > 73)) \]

---

**V. CONCLUSIONS**

This paper proposed a novel SMC-based framework that enables quantitative performance evaluation of Hybrid AADL designs considering various uncertain factors caused by physical environments. We introduced a lightweight language extension to AADL called Uncertainty annex for the stochastic behavior modeling. By using our proposed transformation rules, the uncertainty-aware Hybrid AADL designs can be automatically converted into NPTA models. Based on the statistical model checker UPPAL-SMC, our framework enables automated evaluation of Uncertain Hybrid AADL designs against various complex performance and safety queries. Comprehensive experiment results carried on the CTCS-3 MA scenario demonstrate the efficacy of our approach.
